In summary: DIn summary, the circuit shown has two capacitors in series with a resistor. At time $t=0$, the switch is closed and the initially charged capacitor, C_1 , discharges while the uncharged capacitor, C_2 , charges. The voltage across C_1 at a much later time is equal to the initial voltage of C_1 divided by the sum of C_1 and C_2 . The energy stored in C_1 and C_2 ...

It is worth noting that both capacitors and inductors store energy, in their electric and magnetic fields, respectively. A circuit containing both an inductor (L) and a capacitor (C) can oscillate without a source of emf by shifting the energy stored in the circuit between the electric and magnetic fields. Thus, the concepts we develop in this section are directly applicable to the ...

capacitor bank. The initial circuit is made through the pre-insertion resistor in an SF6 environment. The resistor is then shunted as the main contacts close. Properly sized closing resistors will limit the voltage transients to 1.2 per unit (1.2 X system voltage) and reduce current transients up to 90%. Both current and voltage transients are reduced to levels that should be ...

We seek to determine everything there is to know about the circuit (charge on the capacitor (Q), current through the resistor (I), etc.) at a time (t) if the switch is closed at time ($t=0$). Start by using Kirchhoff's loop rule to relate the voltage differences across the two components at some arbitrary time (t). Let's label the current so that it is going in the direction we know it ...
