

When the capacitor is connected to the battery, the energy stored in the air-filled capacitor is U = ½ CV 2, and the charge on each plate is q = CV. When the capacitor is filled with the dielectric liquid, its capacitance becomes kC, where k is the dielectric constant of the liquid. This increases the charge stored on each plate to kCV.

The factor by which the dielectric material, or insulator, increases the capacitance of the capacitor compared to air is known as the Dielectric Constant, k and a dielectric material with a high dielectric constant is a better insulator than a dielectric material with a lower dielectric constant. Dielectric constant is a dimensionless quantity ...

When we find the electric field between the plates of a parallel plate capacitor we assume that the electric field from both plates is $fE=\frac{\sin \{2epsilon_0\}}{1}$ The factor of two in the denominator comes from the fact that there is a surface charge density on both sides of the (very thin) plates.

Inner sphere is grounded. a) grounding the outer surface of the inner sphere. If you ground the outer surface of the inner sphere, the inner sphere becomes irrelevant and you get single spherical capacitor (the other one at infinity) of radius b. The capacitance is now \$4piepsilon_{0}b\$. b) grounding the inner surface of the inner sphere

As a rule of thumb, a capacitor's plates have opposite and equal charges. This means that the grounded plate has the opposite charge of the isolated (charged) plate, even though it's voltage is zero. This charge, yes, will be mostly located on the surfaces or other edges. It's the electric field from the isolated plate that does this.

For an uncharged capacitor connected to ground the other pin (the side of the switch) is also at ground potential. At the instant you close the switch the current goes to ground, that''s what it sees. And the current is the same as when you would connect to ground without the capacitor: a short-circuit is a short-circuit.

Ignore inner and outer surfaces. There is just one surface. Imagine a single, infinite plane with some positive charge density. You can easily show there would be an electric field of constant strength*, perpendicularly out of the plane all the way to infinity on both directions.. Now imagine a single, infinite plate with the same negative charge density.

We know that electric flux is given by \$phi =E.A\$ \$=EA cos theta\$ \$=EA\$ since electric field is constant in magnitude on the Gaussian surface and is perpendicular to this surface.

Because k k is greater than 1 for dielectrics, the capacitance increases when a dielectric is placed between the capacitor plates. The dielectric constant of several materials is shown in Table 18.1.

Imagine a capacitor with one plate connected to the ground and another plate to the positive pole of a battery whose negative pole is also connected to the ground. The positive charges that gathers on the upper non-grounded plate of the capacitor attracts an equal, but opposite in sign, charge on the lower plate of the capacitor.

A capacitor is an electrical component that stores energy in an electric field. It is a passive device that consists of two conductors separated by an insulating material known as a dielectric. When a voltage is applied across

the conductors, an electric field develops across the dielectric, causing positive and negative charges to accumulate on the conductors.
