Aside from straightforward batteries, the discharge rate finds use in capacitors of power conditioners. These conditioners protect electronics from surges in voltage and current work by eliminating electromagnetic ...

As it turns out, the rate of voltage change across the capacitor is proportional to the current flowing through the terminals (and inversely proportional to the capacitance). To get the voltage across an ideal capacitor (even a tiny one) to change instantaneously would thus require infinite current.

\$begingroup\$ I don't think this will completely discharge the capacitor, at least not through the transistor. You need the voltage across R_6 to be about 0.6V if the transistor is going to be active. That means the voltage across R_5 will be about 10V, and ...

The capacitor discharge when the voltage drops from the main voltage level which it connected to like it connected between (5v and GND) if voltage drops to 4.1v then the capacitor discharge some of its stored charge,the drop in voltage may caused by many effects like increase in a load current due to internal resistance of non-ideal source .

When a capacitor discharges through a simple resistor, the current is proportional to the voltage (Ohm's law). That current means a decreasing charge in the capacitor, so a decreasing voltage. Which makes that the current is smaller. One could write this up as a differential equation, but that is calculus.

What this means is simple! The voltage across capacitor will change linearly with time. The "rate" of change (or "slope") depends on the current magnitude and the capacitance: The bigger the capacitance the slower voltage changes. The bigger the current the faster voltage changes.
